

# Model-based matching for causal inference in observational studies

Kellie Ottoboni  
with Philip B. Stark

Department of Statistics, UC Berkeley

Draft February 25, 2016

# Observational Studies vs Experiments

- **Problem:** Estimate the causal effect of a treatment on outcome of interest
- In randomized experiments, treatment is assigned to individuals at random.
- In observational studies, the way individuals select into treatment groups is unknown.

# Observational Studies vs Experiments

- **Problem:** Estimate the causal effect of a treatment on outcome of interest
- In randomized experiments, treatment is assigned to individuals at random.
- In observational studies, the way individuals select into treatment groups is unknown.

# Matching

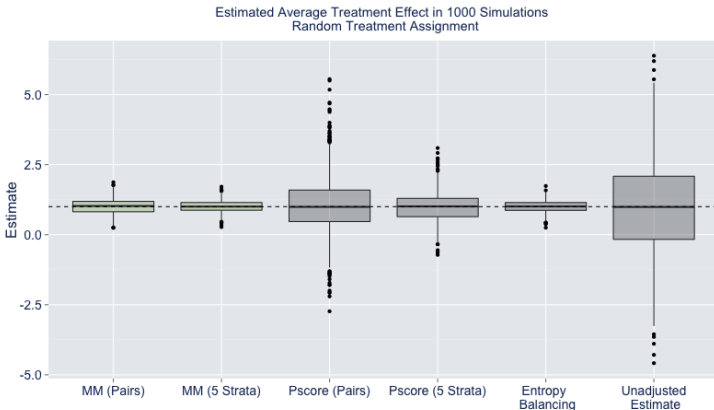

- **Ideal:** group individuals by important confounders to estimate subgroup treatment effects and then average over subgroups
- **Reality:** many covariates, perhaps continuous, make it difficult to stratify

- **Solution:** use a one-dimensional score to match or group individuals
- Stratify according to the “best” prediction of the response,  $\hat{Y}$ , based on all covariates except for the treatment

# Estimation

- Under standard assumptions (conditional independence of treatment and potential outcomes given  $X$ ), the **average treatment effect** is nonparametrically identified
- Estimate it using the difference in average residuals,  $Y - \hat{Y}$ , between treated and controls

# Hypothesis testing: example

- Use stratified permutation test to test the **strong null hypothesis** of no treatment effect whatsoever
- Test for association between residuals  $Y - \hat{Y}$  and treatment

Female Male

# Future Directions

- Do different test statistics give greater power when the treatment effect is nonlinear?
- What is the optimal way to stratify?
- How to quantify uncertainty – standard errors and confidence intervals?
